A stochastic background of gravitational waves could result from the random superposition of an extremely large number of unresolved and independent gravitational-wave (GW) emission events. Such a background is analogous to the cosmic microwave background radiation (CMBR), though its spectrum is unlikely to be thermal. The emission events could be the result of cosmological processes, as with the CMBR, but occurring much earlier after the big bang—e.g., during inflation. The events could also be due to more recent astrophysical processes. Placing upper limits on or detecting the energy density of a stochastic background of gravitational waves is one of the long-term goals of GW detectors.

The stochastic background spectrum is typically characterized in terms of a dimensionless quantity $\Omega_{GW}(f)$: the GW energy density per unit logarithmic frequency, divided by the critical energy density $\rho_c$ to close the Universe. The critical density, and thus $\Omega_{GW}(f)$, depend on the Hubble expansion rate $H_0$; in this Letter, all bounds on $\Omega_{GW}(f)$ will be for $H_0 = 72$ km sec$^{-1}$ Mpc$^{-1}$ [1]. We search for power laws of the form $\Omega_{GW}(f) = \Omega_0 (f/100 \text{ Hz})^{\alpha}$. The choices of $\alpha$ are motivated by potential source models [2]: ($\alpha = 0$) predicted by inflationary or cosmic string models; ($\alpha = 2$) rotating neutron stars; ($\alpha = 3$) pre-big-bang cosmology.

Previous direct measurements of a stochastic background, in the $\sim 10$ Hz to $\sim 10^4$ Hz band accessible to Earth-based detectors, have been limited to establishing upper limits on $\Omega_{GW}(f)$ greater than unity, with the best and most recent result using the Laser Interferometer Gravitational-Wave Observatory (LIGO)’s first science data finding $\Omega_0 < 44$ [3]. (The best upper limit from acoustic detectors is $\Omega_0 < 120$ at 907 Hz, from a cross-correlation measurement between the Explorer and Nautilus cryogenic bar detectors [4].) At much lower frequencies, spacecraft Doppler tracking has established...
of the intersite pairs only; the H1-H2 measurement, though tible to a much broader range of potentially correlated paths through which instrumental correlations could arise. 

For the colocated detector pair, H1 and H2, there are only a few segments in the space-time metric due to a passing GW, measuring directly the GW strain amplitude. While the detectors are still being commissioned to perform at their designed sensitivity, several dedicated data collection runs have been performed. The detector configuration and performance during LIGO’s first science run (S1) is described in Ref. [8]. In this analysis, we use data from the third science run (S3), carried out from 31 October 2003–9 January 2004, with significantly improved sensitivity compared to previous runs. Figure 1 shows reference amplitude spectra of equivalent strain noise for S3.

To search for a stochastic background, we cross correlate the strain data from a pair of detectors, taking advantage of the fact that the instrumental noise of one interferometer will, in general, be uncorrelated with that of the other interferometers. This is more clearly the case for the widely separated interferometer pairs (i.e., L1 paired with H1 or H2), for which there are only a few paths through which instrumental correlations could arise. The H1-H2 cross correlation, on the other hand, is susceptible to a much broader range of potentially correlated instrumental noise sources. This Letter presents an analysis of the intersite pairs only; the H1-H2 measurement, though of magnitude below previous limits in this frequency band.

LIGO is composed of three GW interferometers at two sites: the 4 km H1 and 2 km H2 detectors, colocated at Hanford, WA, and the 4 km L1 detector, located in Livingston Parish, LA [7]. Each detector is a power-recycled Michelson interferometer, with 4 km (or 2 km) long Fabry-Perot cavities in each of its orthogonal arms. These interferometers are sensitive to quadrupolar oscillations in the space-time metric due to a passing GW, measuring directly the GW strain amplitude. While the detectors are still being commissioned to perform at their designed sensitivity, several dedicated data collection runs have been performed. The detector configuration and performance during LIGO’s first science run (S1) is described in Ref. [8]. combined to produce a final cross-correlation estimator $Y_{\text{opt}}$ that maximizes the signal-to-noise ratio and has variance $\sigma^2_{Y_{\text{opt}}}$:

$$Y_{\text{opt}} = \frac{1}{T} \sum_{j} \sigma^2_{Y_j} Y_j / \sigma^2_{Y_{\text{opt}}}, \quad \sigma^2_{Y_{\text{opt}}} = \frac{1}{T} \sum_{j} \sigma^2_{Y_j}. \quad (5)$$

The normalization factor $\mathcal{N}$ is defined such that the point estimate of $\Omega_\alpha$ and its standard deviation are given by:

$$\hat{\Omega}_\alpha = Y_{\text{opt}} / T, \quad \sigma_{\hat{\Omega}_\alpha} = \sigma_{Y_{\text{opt}}}/T. \quad (Thus, Y_j, Y_{\text{opt}}, \text{and } \mathcal{N} \text{ all have dimensions of time.})$$

Before computing the cross correlation, each 60 sec data interval is decimated (from 16,384 to 1024 Hz), high-pass filtered (40 Hz cutoff), and Hann windowed. The windowing step protects against spectral leakage of strong lines that may be present in the data [10], but at the same time a Hann window reduces the effective length of the interval by nearly a factor of 2 (approximately the mean value of the Hann window). To recover the loss in signal to noise, the data intervals are overlapped by 50%, so that each data point receives full weighting in the analysis (except for end effects). This introduces some correlation between the point receives full weighting in the analysis (except for end effects). This introduces some correlation between the $Y_j$ and $\sigma_{Y_j}$ for adjacent values of $I$, complicating the formulas for the optimal estimator and its variance, derivations of which may be found in Ref. [11].

The detectors’ strain noise power spectral densities (PSDs) are estimated for each interval in order to calculate the optimal filter $\hat{Q}(f)$. Welch’s modified periodogram method of PSD estimation is used, averaging 58 periodograms formed from 4 sec long, 50% overlapping data windows [10]. The PSD for interval $I$ is formed from the two 60 sec data intervals preceding and following, but excluding the data within, interval $I$. This technique eliminates a bias (underestimate) in the cross correlation that would otherwise exist, due to nonzero covariance between the $\hat{s}_1 \cdot \hat{s}_2$ cross-spectrum and the corresponding power spectra. However, short-term changes (typically increases) in detector noise may produce outliers, because excess instrumental noise within interval $I$ is not reflected in its PSD. This is addressed by applying a consistency test on $\sigma_{Y_j}$: If the $\sigma_{Y_j}$ calculated using the average of the PSDs for interval $I-1$ and interval $I+1$ as described above differs from that calculated from interval $I$ by more than 20%, the data in interval $I$ are not used in the cross-correlation analysis. Approximately 20% of the data were rejected by this cut.

To compute the cross correlation [Eq. (1)], the raw detector data are calibrated, in the frequency domain, into strain units using interferometer response functions. These functions are calculated once per 60 sec, using a measurement of the response of an interferometer to a sinusoidal calibration force, averaged over 60 sec. The frequency domain values of $\{\hat{s}_1, \hat{s}_2\}$, given at a frequency spacing of $1/60$ Hz, are binned to the resolution of the optimal filter (frequency spacing of $1/4$ Hz), and the integrations in Eqs. (1) and (3) are performed for the different $S_{GW}(f)$.

As was important in the earlier analysis of Ref. [3], frequency bins corresponding to known or potential instrumental correlation artifacts are excluded from the frequency domain integrations. An obvious example of intersite correlations comes from the 60 Hz ac supply lines used to power the detectors. The 60 Hz modulation and its harmonics are present to some degree in the detector electronics and, thereby, infiltrate the strain output signal (as Fig. 1 shows). Between L1 and H1.2, the power lines tend to be well correlated over time scales shorter than ~100 sec, with ever-decreasing correlation over longer times. To exclude the possibility of any residual long-term power line correlation, the (60 Hz, 120 Hz, . . .) bins are excluded from the integration.

Another narrow-band source of instrumental correlation stems from imperfections in the detectors’ data acquisition systems. The peaks in Fig. 2, at multiples of 16 Hz, were produced by slight but periodic corruption of the data at each site. The data acquisition timing at each site is controlled by clocks synchronized to the 1 pulse-per-second signals produced by global positioning system receivers. The 16 Hz periodicity of the data corruption was controlled by these clocks, resulting in persistent intersite correlations at multiples of 16 Hz. Thus, the (16 Hz, 32 Hz, . . .) bins are also excluded from the integration. (After S3, the offending clock modules were identified and the problem was corrected.) For a frequency range of, e.g., 70–250 Hz, the removal of 1/4 Hz bins at multiples of 60 and 16 Hz corresponds to a loss of ~2% of the total bandwidth.

$\text{FIG. 2. Coherence between H1 and L1 during S3, showing a few small, but significant, coherent peaks at multiples of 16 Hz.}$

The horizontal line corresponds to the statistical expectation value of $1/N_{\text{avg}} = 3.3 \times 10^{-5}$, where $N_{\text{avg}}$ is the number of periodogram averages. The inverted triangles at the top of the graph indicate the discrete frequencies omitted from the analysis. The inset histogram shows that the coherence values (Γ) follow the expected exponential distribution (dashed line).
Results.—For each power law searched for, we calculate the optimal cross-correlation statistic and its variance [Eq. (5)]. The H1-L1 results are summarized in Table I. The H2-L1 correlation is approximately a factor of 7 less sensitive than H1-L1, due to the higher noise level of H2; the H2-L1 results are thus not used for the upper limits results (and are not shown), but they are consistent, within their error bars, with the H1-L1 results.

Systematic errors due to unresolved time variations in the interferometers’ calibration and power spectra were investigated and determined to be small compared to the statistical error \( \sigma_{\Omega_a} \). Phase calibration uncertainties and timing errors are also negligible. Not negligible are interferometer amplitude calibration uncertainties, estimated as a \( \pm 11\% \) (\( \pm 15\% \)) frequency-independent uncertainty in the strain response magnitude for H1 (L1).

We construct a Bayesian posterior probability distribution for \( \Omega_a \) using the optimal point estimate \( \hat{\Omega}_a \) and statistical error \( \sigma_{\Omega_a} \), marginalizing over the unknown calibration magnitudes (see, e.g., [12]). The prior probability distribution for \( \Omega_a \) is taken to be uniform from 0 to 0.02 (the maximum value corresponding to the largest background that is still consistent with the lowest single interferometer strain noise); the prior distributions for the calibration magnitudes are taken to be uniform between 1 \( \pm 0.11 \) (for H1) and 1 \( \pm 0.15 \) (for L1). The 90% probability upper limit is then that value of \( \Omega_a \) for which 90% of the posterior distribution lies between 0 and the upper limit. (The upper limit is relatively insensitive to reasonable changes in the priors.) A uniform prior was chosen for \( \Omega_a \) because of its simplicity and to allow for easy comparison with previous observations. Such a prior favors higher values of \( \Omega_a \) and, therefore, generates a somewhat more conservative upper limit.

The estimates for \( \Omega_a \) are entirely consistent with no stochastic background, within the sensitivity of the measurement. Furthermore, the cross-correlation spectrum [i.e., the integrand of Eq. (1)] shows no distinct features (see Fig. 3), and the \( \approx 26,000 \) values of \( Y_f \), with mean removed and normalized by the \( \sigma_{Y_f} \), follow the expected normal distribution.

The data analysis pipeline was validated by checking its performance on fake stochastic signals injected into the data, using a combination of both software and hardware injections [3,13]. The amplitudes of the measured and injected signals agreed to within the statistical error for injections down to a level of \( \Omega_1 = 1 \times 10^{-4} \).

![FIG. 3. The estimate \( \hat{\Omega}_{a\alpha} \), for H1-L1 and \( \alpha = 0 \): (a) as a function of the amount of data analyzed. The shaded region shows the \( \pm 2\sigma_{\Omega_a} \) band on \( \hat{\Omega}_a \). (b) The real part of the H1-L1 cross-correlation spectrum, in arbitrary units. (c) As a function of the frequency range analyzed. The shaded region shows the \( \pm 2\sigma_{\Omega_a} \) band on \( \hat{\Omega}_a \), cumulative in frequency from 69 Hz to \( f \).](image)

### Table I. Results of the cross correlation of LIGO’s H1 and L1 interferometers, analyzed for a potential power-law stochastic background of the form: \( \Omega_{GW}(f) = \Omega_a(f/100 \text{ Hz})^\alpha \). The frequency range for each \( \alpha \) is the band that contributes 99% of the full sensitivity, as determined by the inverse variance. All results correspond to the specified band and an observation time of 218 h. 90%-confidence Bayesian upper limits on \( \Omega_{GW}(f) \) [also expressed as limits on the strain noise density \( S_{GW}(f) \)] are calculated from the point estimates and statistical errors, marginalizing over a \( \pm 11\% \) and \( \pm 15\% \) uncertainty in the calibration magnitude of the H1 and L1 detectors.

Conclusions.—The energy density in a primordial background of GWs is constrained by big-bang nucleosynthesis theory, giving a conservative bound of: $\int d(\ln f)\Omega_{GW}(f) < 1.1 \times 10^{-5}$ [2]; if all the GW energy were concentrated in our sensitive band, this is still $60 \times$ below the limit set here. A background from astrophysical sources would be generated at much later cosmic times and, thus, not be subject to the above bound. In the LIGO band, such a background could be generated by the superposition of many short-lived signals, such as supernova bursts and rotating neutron stars (in the tens to hundreds of hertz band). Uncertainties in the theoretical models are large, though the most optimistic predictions peak at $\Omega_{GW}(f) \sim 10^{-7}$ [2]. Nonetheless, the results presented here provide direct, measured limits to a stochastic background, that, in terms of energy density, are nearly $10^5$ lower than previous measurements. Eventually, with 1 year of data at design sensitivity, the LIGO detectors will be sensitive at a level several times below the nucleosynthesis bound.
